

Elementary Sequence Analysis

Brian Golding, Dick Morton and Wilfried Haerty

Department of Biology
McMaster University
Hamilton, Ontario
L8S 4K1

These notes are in Adobe Acrobat format (they are available upon request in other formats) and they can be obtained from the website <http://helix.biology.mcmaster.ca/courses.html>. Some of the programs that you will be using in this course and which will be run locally can be found at <http://evol.mcmaster.ca/p3S03.html>.

The “blue text” should designate links within this document while the “red text” designate links outside of this document. Clicking on the latter should activate your web browser and load the appropriate page into your browser. If these do not work please check your Acrobat reader setup. The web links are accurate to the best of our knowledge but the web changes quickly and we cannot guarantee that they are still accurate. The links designated next to the JAVA logo, , require that JAVA be installed on your computer.

These notes are used in Biology 3S03. The purpose of this course is to introduce students to the basics of bioinformatics and to give them the opportunity to learn to manipulate and analyze DNA/protein sequences. Of necessity only some of the more simple algorithms will be examined.

The course will hopefully cover ...

- databases of relevance to molecular biology.
- some common network servers/sites that provide access to these databases.
- methods to obtain sequence analysis software and data.
- methods of sequence alignment.
- methods of calculating genetic distance.
- methods of phylogenetic reconstruction.
- methods for detecting patterns and codon usage.
- methods for detecting gene coding regions.

The formal part of the course will consist of two approximately one hour lectures each week. Weekly assignments will be provided to practice and explore the lecture material. In addition there will be an optional tutorial to help students with these assignments or other problems. These assignments will be 40% of your grade and three, in class quizzes will make up the remainder.

We would appreciate any comments, corrections or updates regarding these notes.

Chapter 8

Database Searching

8.1 Are there homologues in the database?

The following are some of the common programs currently being used to search the databases to find sequences similar to a specific query sequence provided by the user. In addition to finding out the identity of an unknown sequence they are also useful to find homologues and ancestral sequences that have similar or related functions/sequences.

8.1.1 FASTA

To search through the whole genetic sequence database can take a great deal of time due to its enormous size. If some operation must be performed on each sequence in turn then this can take even longer. One such example is to look throughout the whole database for homologous or similar sequences. To do this, special programs have been developed to speed the search. The first amongst these programs was a program called **FASTA** written by W.R. Pearson and D.J. Lipman (1988, PNAS 85:2444-2448).

It is possible to run this program on remote machines. The obvious choice for such a remote machine would be one that has access to the latest sequence information. Both EMBL and DDBJ have permitted this type of access and have implemented FASTA type searches through their machines (NCBI prefers to use BLAST - see below).

There are several flavours to FASTA: *fasta* scans a protein or DNA sequence library for sequences similar to a query sequence. *tfasta* compares a protein query sequence to a translated DNA sequence library. *lfasta* compares two query sequences for local similarity between them and shows the local sequence alignments. *plfasta* compares two sequences for local similarity and plots the local sequence alignments. Two recent flavours *fastx* and *fasty* (Pearson *et al.* 1997 *Genomics* 46:24-36) permit comparison of a DNA sequence translated in all six frames to the protein databases. The 'x' form takes a DNA query sequence and translates it in all frames and then permits gaps between the resulting amino acids. The 'y' form more generally permits gaps within and between codons. The related *tfastx* and *tfasty* forms compare a protein query sequence to a DNA database by translating the DNA database in all six frames.

I will illustrate what a FASTA type of search is and what the results look like with an example. Basically the idea is to search through the complete database for any possible similar sequence.

8.1.1.1 Instructions

To carry out this type of search on the EMBL server the following must be done. Either point your web browser to **FASTA3** and fill out the appropriate forms or set up a file containing the following

```
LIB UNIPROT
WORD 1
LIST 50
TITLE HALHA
```

```
HISTOGRAM yes
SEQ
PTVEYLNYETLDDQGWDMDDDDLFEKAADAGLDGEDYGTMEVAEGEYIIEAAEAQGYDWP
FSCRAGACANCASIVKEGEIDMDMQIILSDEEVEEKDVRLTCIGSPADEVKIVYNAKHL
DYLQNRVI
```

The first line contains the data library files to be searched (in this case all known protein entries). For protein searches this field may be one of

UniProt	A non-redundant collection of all proteins
UniRef100	As for UniProt but eliminate identical proteins
UniRef90	As for UniProt but eliminate proteins > 90% identical
UniRef50	As for UniProt but eliminate proteins > 50% identical
UniParc	As for UniProt but include archived proteins (shows changes to an entry).
swiss-prot	Proteins in the SwissProt database
ipl	Proteins in the International Protein Index
prints	Proteins in the FingerPrints database
sgt	Proteins in the Structural Genomics Targets database
pdb	Proteins in the 3D structural database PDB at Rutgers
imgthlap	Proteins in the Immunogenetics Database
Euro Patents	Proteins in the European patents database
Japan Patents	Proteins in the Japanese patents database
USPTO Patents	Proteins in the American patents database

For nucleotide searches this field may be one of

EMBL	The entire EMBL database
FUNGI	Subsection of EMBL.
INVERTEBRATES	
HUMAN	
MAMMALS	
ORGANELLES	
BACTERIOPHAGE	
PLANT	
PROKARYOTES	
RODENTS	
MOUSE	
STSs	Sequence Tagged Sites
SYNTHETIC	
UNCLASSIFIED	
VIRUSES	
VERTEBRATES	
ESTs	Expressed Sequence Tags
GSSs	Genome Survey Sequences
HTGs	High throughput Genomics sequences
PATENTS	
VECTORS	
EMBLNEW	Sequences new since the last major database release
EMBLALL	EMBL + EMBLNEW
IMGTLLIGM	Immunoglobulins and T cell receptors database
IMGTHLA	Human Major Histocompatibility Complex (MHC/HLA) database
HGVBASE	Human Genome Variation database

The second line gives the word size or k-tuple value (more on this below). The third line says to LIST on the output the top 50 scores. The TITLE line is used for the subject of the mail message. Finally SEQ implies that everything below this line to the end of the message is part of the sequence. In this case the sequence is the protein sequence of the ferredoxin gene of *Halobacterium species NRC-1*.

The remaining options are - LIST n, n top scores listed in the output [50]. ALIGN n, align the top n to the query sequence [10]. ONE, compare only the given strand to the database, the default is to use the complementary strand as well. PROT will force your query sequence to be a protein (small protein sequences may be otherwise misinterpreted as DNA). PATH string mails the results back to string rather than the originator of the message.

After creating this file, mail the file by electronic mail to fasta@ebi.ac.uk and the results will be sent back to you by electronic mail. Alternatively simply point your web browser to FASTA3 and fill in the forms (they have the same options). Please, as a courtesy to others using the system please send only one job at a time. Many other people from all over the world are using these servers and the FASTA program is quite computer intensive despite its speed.

8.1.1.2 FASTA output

An example of the output is shown below. The input file is specifying the *Halobacterium species NRC-1* ferredoxin amino acid sequence to search the SWISS-PROT database.

```

FASTA searches a protein or DNA sequence data bank

Function used was FASTA [version 3.4t23 March 18, 2004]

```

8.1.1.3 FASTA format

The textual output as shown above is only one possible output available. In addition to the textual output, you can request an MVIEW (a multiple alignment view) as in Figure 8.1 or a visual fasta view (a graphical version of the significance) as in Figure 8.2.

The textual output from the FASTA search begins with some informational messages. This includes the reference that you should cite, the version number of the program and the libraries that were searched. In this case, an optional histogram (lying on its side) has been requested of the number of sequences found with various scores. Each equal symbol in this histogram is an indicator of 2608 sequences and the asterisk indicates the expected number. The tail of the distribution is expanded in the inset. Here each equal symbol represents 13 sequences. This histogram gives you an indication of how similar the query sequence is to some of the database sequences. For a query sequence that has found a significant match, it should be well out of the tail of the distribution. In this example there are many sequences with scores larger than 120 and they are more frequent than expected by chance. These are related ferredoxin sequences from other species.

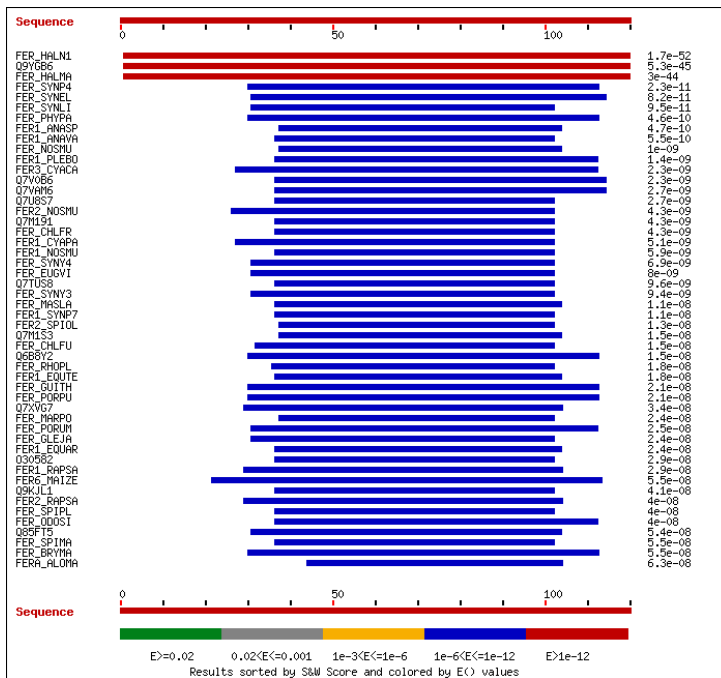

Next comes some information about the size of the database searched (note the size of the numbers) and some statistics about the search. Next comes a section that lists the sequences (along with their locus names) that have the best scores. Finally there is a section that lists the alignments that have been found by the program.

To carry out a database search in this manner, the algorithm first establishes a table containing words from the database sequences of variable length (e.g. ATCGGA, ACCCTG, GTCACA, ... for nucleotides or MK, RS, CP, ... for proteins). This type of preprocessing of the entire database is necessary to speed the subsequent search. This table is then sorted in alphabetical order and allows matching words (from the query sequences) to be found rapidly. The length of these words is

Figure 8.1: The MVIEW output from <http://www.ebi.ac.uk/fasta> for the ferredoxin data

Figure 8.2: The VISUALFASTA output from <http://www.ebi.ac.uk/fasta> for the ferredoxin data

set by the WORD or k-tuple parameter value. By default it is 6 for nucleic acids and 2 for amino acid searches. A lower k-tuple will give a more sensitive search but will take much longer. Although a range of 3 to 6 is permitted for nucleic acids a lower value is generally unnecessary. All places in the query sequence are determined where the k-tuple from both sequences agree perfectly. Then those regions with the highest density of these identities are found.

In comparing a query sequence to the database three scores are calculated for each and every entry in the database. These scores are *init1*, *initn* and *opt*. An *init1* score is assigned to each of these regions of high similarity after the regions are extended at the ends to include regions shorter than the length of a k-tuple and after using a BLOSUM50 matrix (alternative distance matrices are available – more on these later) to score mismatches.

Groups of larger regions are attempted to be joined together and an *initn* score is generated from these. This is done by setting *initn* equal to the sum of the two *init1* scores for each region (the final *init1* score of a sequence is the maximum *init1* score from all interior regions). A constant of 20 is then subtracted as a joining penalty. If the *initn* score is less than one of the *init1* scores it is discarded, the regions are not joined and the *initn* score will be equal to the maximum *init1* score (hence *initn* is greater than or equal to *init1*).

Sequences that have an *initn* score larger than a cutoff value (usually 50 but this can be altered with a “LIST n” command in the query file) are then used for a Smith-Waterman alignment (see the section on alignments) and an *opt* score is generated from these alignments. Only the region considered significant by the program is displayed. In these alignments, the name of the sequence will be presented, the scores, and the percent similarity over the region aligned. In general the length of the region aligned is a better indicator of homology than is the percent similarity. This is because large percentages can be found in short regions just by chance. A ‘:’ is used to indicate a complete match, a ‘.’ to indicate a conservative amino acid replacement, and a ‘-’ to indicate a deletion/insertion.

Note that the *opt* score can be lower than the *initn* score. This will happen when one sequence has two (or more) regions of high similarity separated by regions that have little/no homology. The two regions are joined with high *init1* scores and the *initn* score is high because the gap penalty/join penalty is not sufficiently large. In contrast sequences with a large number of poorly similar regions will have low *init1* scores but high *initn* scores and then low *opt* scores. In general, unless a very short sequence is used, the *init1* score should be much improved by the *opt* score for truly significant sequences. Lastly a z-score based on estimates of the statistical significance of the *opt* scores is presented. This estimates the probability of obtaining *opt* scores as good or better by chance between unrelated sequences (see below).

Remember to remove repetitive sequences from your query otherwise you will get a lot of false hits. The FASTA program itself can be obtained via anonymous ftp if desired.

8.1.1.4 Statistical Significance

Since version 2.0 of the FASTA program distribution, FASTA, TFASTA, and SSEARCH will provide estimates of statistical significance for library searches. Work by Altschul, Arratia, Karlin, Mott, Waterman, and others (see [Altschul *et al.* 1994 Nature Genetics 6:119-129](#) for an excellent review) shows that local sequence similarity scores follow an extreme value distribution. The probability of a database match score larger than x arising by chance alone is therefore

$$P(s \geq x) = 1 - e^{-e^{-\lambda(x-u)}}$$

where for ungapped alignments

$$u = \frac{\ln(Kmn)}{\lambda}$$

and m, n are the lengths of the query and library sequence and K and λ are constants that depend on the substitution scores and the sequence compositions. This formula can be rewritten as:

$$1 - e^{-Kmn(e^{-\lambda x})}$$

which shows that the probability of observing larger scores for unrelated library sequences increases logarithmically with the length of the library sequence (Pearson - FASTA documentation).

FASTA and SSEARCH produce gapped alignments and hence use a simple linear regression against the log of the library sequence length to calculate a normalized “z-score” with mean 50, regardless of library sequence length, and variance 10.

These z-scores can then be used with the extreme value distribution and the poisson distribution (to account for the fact that each library sequence comparison is an independent test) to calculate the expected number of library sequences required to obtain a score greater than or equal to the score obtained in the search (Pearson - FASTA documentation).

The expected number of sequences is plotted in the histogram using an '*'. Since the parameters for the extreme value distribution are not calculated directly from the distribution of similarity scores, the pattern of '*s in the histogram gives a qualitative view of how well the statistical theory fits the similarity scores calculated by FASTA and SSEARCH. For FASTA, optimized scores are calculated for each sequence in the database and the agreement between the actual distribution of "z-scores" and the expected distribution based on the length dependence of the score and the extreme value distribution is usually very good. Likewise, the distribution of SSEARCH Smith-Waterman scores typically agrees closely with the actual distribution of "z-scores." The agreement with unoptimized scores, $ktup = 2$, is often not very good, with too many high scoring sequences and too few low scoring sequences compared with the predicted relationship between sequence length and similarity score. In those cases, the expectation values may be overestimates (Pearson - FASTA documentation).

The statistical routines assume that the library contains a large sample of unrelated sequences. If this is not the case, then the expectation values are meaningless. Likewise, if there are fewer than 20 sequences in the library, the statistical calculations are not done (Pearson - FASTA documentation).

The online [FASTA - nucleotide](#) / [FASTA - protein](#) help at EBI can be consulted for further information.

8.1.2 BLAST

While FASTA is a sensitive and rapid algorithm to search for similar sequences in the database it is not without problems. Because its initial step looks for perfect matches it might be less sensitive to more distantly related sequences that have functional homology but no longer retain complete identity. If an amino acid sequence has had many conserved replacements but no longer has identities then the FASTA algorithm might not identify these as well as it should. Fortunately, alignments where there are extensive regions of low but not exact similarity are rare enough that a small WORD or k-tuple size will pick up most regions.

A different algorithm which improves upon FASTA in speed is termed **BLAST** (Basic Local Alignment Search Tool). This began with a statistical paper by [Karlin and Altschul \(PNAS 87:2264-2268, 1990\)](#) who developed a rigorous method to obtain the probabilities of matches with a query sequence given that no gaps are permitted. This permits the use of larger WORD or k-tuple sizes with the concomitant increase in speed but permitting inexact matches between WORDs. The statistical developments permit this to be done without loss of sensitivity and allow rigorous statistical statements to be made about the matches found.

As a result of these developments [Altschul, Gish, Miller, Myers and Lipman \(J.Mol.Biol. 215:403-415, 1990\)](#) created the **BLAST group** of programs. These algorithms find ungapped, locally optimal sequence alignments. There are several versions of the BLAST programs. Some are

BLASTN - nucleotide query of the nucleotide database.

BLASTP - protein query of the protein database.

BLASTX - translate DNA to protein and query protein database.

TBLASTN - protein query of the translated nucleotide database.

TBLASTX - translate DNA to protein and query the translated nucleotide database.

PHI-BLAST - pattern-hit initiated program takes a user search pattern and finds proteins similar.

PSI-BLAST - use position-specific iterative score matrices to search for protein "motifs" or "profiles".

MEGA-BLAST - nucleotide query of the nucleotide database.

discontiguous MEGA-BLAST - nucleotide query of the nucleotide database.

The last two use a different algorithm than does BLASTN. The program MEGA-BLAST uses a "greedy algorithm" for nucleotide sequence alignment search and is designed to find sequences that differ slightly from the query sequence. Hence is best at identifying something "similar" in the database without concern about distant homologies. It is much faster than BLASTN and by default uses a much large k-tuple. The program **discontiguous MEGA-BLAST** increases

sensitivity to diverged sequences by using a discontinuous word as the initial match from which extensions are performed (see below).

To carry out this type of search go to the NCBI **BLAST** web server, select the desired program and fill out the forms.

Most of the options will take standard default values. The database for example, has a default of “nr”. This means that it will search the non-redundant database (it includes sequences from PDB, GenBank, GenBank updates, EMBL and EMBL updates or sequences from PDB, SWISS-PROT, PIR, GenPept and GenPept updates) but there are many others that can be chosen instead. In addition you can choose to search only specific groups of organisms or to search sequences that originated from only one organism. Filter’s will mask parts of your query so that things like repetitive elements are ignored (filter seq - will exclude regions of low compositional complexity, filter dust - is a modernized filter version that at the time of this writing has not yet been described in the literature. Other filter’s will exclude regions with repetitive elements). It is also possible to select the number of DESCRIPTIONS n, the number of described matching sequences [100]. ALIGNMENTS n, number of high scoring pairs [50], the EXPECT n, the score such that n sequences should be found by chance alone [10] (a fractional value of one or less will give only output which is statistically unusual, larger values give more output) and the WORD size used for initial matches. Other options are available.

More information about the programs and their output can be obtained from NCBI’s BLAST site including a

- [BLAST overview](#)
- [BLAST FAQs](#)
- [BLAST Program Selection Guide](#)
- [BLAST course](#)
- [BLAST video tutorials](#)
- [BLAST handbook](#)

The BLAST programs themselves can be obtained if desired by anonymous ftp to **NCBI** (with more options possible (and permissible)) and if desired, a network client that works directly through TCP/IP connections (hence, no web browser required) can be obtained as BLASTc13 from the ftp site.

8.1.2.1 BLAST output

Typical BLAST output appears as in Figure 8.3 (this search was done on Jan 19 2002 with an APRT gene from *Mus pahari* as the query).

Each of the blue-highlighted pieces of text are links that leads directly to the entry in the database that matches the query. There is a diagram at the top of the entry that graphically demonstrates the hits and how they align with the query sequence. It is colour coded according to the statistical level of the match. In this diagram regions of low match are in gray hatch-marks. Note that even though the query sequence is in the database, there are these hatch-marks in the first matching sequence. This is because these sequence regions contain low complexity DNA (e.g. [J.C. Wootton, 1994 Comput Chem 18:269-285](#)) that would disrupt the statistical measures of similarity and hence they have been excluded by default from the match (this behaviour can be altered ... see above).

After the listing of hits comes a section that lists the match between the query sequence and the database match.

and finally at the bottom of the entry will be some statistics about the search ...

spicilegus (a closely related species – with a correspondingly closely related APRT sequence) and not surprisingly it has an expect value of 1×10^{-119} . That is, in a database of this size you expect to see 1×10^{-119} other matches as good or better than this one just by chance (effectively zero).

An older search of the same sequence found the same matches and if you continued down the list you would see ...

So as you go down the list you find more APRT genes but also, later on, some oncogene – *c-abl*. So now you get all excited — we have discovered a new class of genes involved in cancer! Major advance ... international acclaim, ... **Nobel Prize!!** But wait, we must be cautious here, what do the statistics say. Well for this *c-abl* gene the match has a probability of 3.6×10^{-27} of occurring by chance alone. So we are home free, that is significant in anyone's statistic book. But no, life is seldom so exciting. As you continue to scan the list, you find cytochrome C, membrane proteins, growth factors, and all sorts of other genes all with apparent significant homology to the query sequence. What is going on?

Remember that BLAST (and any of the other algorithms) search for similarity not of the entire sequence but rather for any piece of the query sequence. Examining the regions of significant match between the database sequences and the query sequence indicates that these are consistently from approximately nucleotides 302 to 431 but not generally outside of this region. This region encodes a very common SINE element in rodents. Hence there is no similarity of the query gene to all these other genes but there is a significant similarity of the B2 SINE element that is inserted into the APRT gene and the B2 SINE elements that have been inserted into the other gene sequences. Be careful of the interpretation of your results — no Nobel prize this time.

Occasionally, other features such as a coiled-coil region or transmembrane regions will cause falsely positive matches to be predicted. In addition, although not a false match, the results of exon shuffling can copy a motif from one protein to another and might lead one to consider that the entire lengths of these two proteins are homologous (and derived evolutionarily from the other) when it is really only the motif that is similar. Sometimes, functional requirements will cause selection to pick on a pattern of amino acids that are similar again without homology.

Another common misuse of BLAST is to search for the most similar sequence to some query sequence. But the algorithm is designed to find similar ungapped subsequences, and to then piece these together. The order in which these sequences are ranked by score may not correspond to the order of overall similarity of the complete sequences, and certainly may not correspond to the phylogenetic history of these sequences (Koski & Golding 2001, *J.Mol.Evol.* 52:540-542). Thus a sequence with a higher score may not be more 'similar' to the query sequence than another sequence with a lower score (more later on what is meant by similarity). It is quite possible for the overall similarity to be greater for a sequence with a lower BLAST score. A sequence may also be more closely related in terms of history to the query than some other sequence with a lower score.

MPsrch Submission Form

MPsrch is a biological sequence comparison tool that implements the true Smith and Waterman algorithm. It runs a search on a HP/COMPAQ cluster, using single and parallelised versions of the software. It allows a rigorous search in a reasonable computational time. MPsrch utilises an exhaustive algorithm, which is recognised as the most sensitive sequence comparison method available, whereas [Blast](#) and [Fasta](#) utilise a heuristic one. As a consequence, MPsrch is capable of identifying hits in cases where Blast and Fasta fail and also reports fewer false-positive hits.

8.1.3 MPsrch

Discontinued

The **MPsrch** server at EBI runs on an HP/COMPAQ computer cluster. It uses the Smith-Waterman local similarity algorithm (see section 6.2.2 for a description of this alignment algorithm) to compare the query sequence versus the Swiss-Prot database. The advantage of this algorithm is that “is recognised as the most sensitive sequence comparison method available, whereas BLAST and FASTA utilise a heuristic one. As a consequence, MPsrch is capable of identifying hits in cases where Blast and Fasta fail and also reports fewer false-positive hits.”. It will only run searches for proteins and not for nucleotides due to the time involved but also due to the discreteness of proteins. The speed achieved by **MPsrch**, is mainly that it is running on a “massively” parallel computer. Because of the use of a parallel computer, it was claimed that “MPsrch is the fastest implementation of the SW algorithm currently available on any machine”. Many molecular biology problems lend themselves to parallel architecture computers. For many problems, intermediate steps can be effectively calculated without the need to know results from previous steps. Each of these independent steps can be given to a different processor and solved on its own. Special software has been developed for parallel computers to manage communication among individual processors and to delegate jobs to each one.

The input sequence

```

DYLQNRVI
```

was given to the website of MPsrch at <http://www.ebi.ac.uk/MPsrch/index.html>. The input webpage for MPsrch is shown in Figure 8.4. It provides several options that you should explore. Note in particular the database search options. In the example used below I selected the database UNIPROT but for initial explorations you should try UNIREF## databases. These eliminate proteins that are within ## percentage of similarity (where ## is 100, 90 or 50). This will speed an already rapid search. .

8.1.3.2 MPsrch format

This particular search took only 5 seconds of CPU time and a total of 101 seconds including input/output. This speed is a great improvement over that achieved by the FASTA algorithm. The web page output is shown in Figure 8.5. . This algorithm is as fast as BLASTP and in addition, it should also give a more sensitive search for distant homologies.

The mean and variance of the distribution of scores from the entire database are calculated. These are used to construct empirical statistics of the predicted number of random matches in the database equal to or better than that found. The algorithm then lists the best scores (50 of them here, the default for NAMES) and then lists more detailed reports for a subclass of these (30 here, the default for ALIGN). For each it calculates the raw score, the percent matches, the predicted number expected, the number of matches, the number of mismatches, the number of partial matches (residue pairs with a positive score in the PAM matrix), the number of indels and the number of gaps. This program considers these two differently in that a single gap can be composed of any number of adjacent indels.

In this case all hits have very small “pred. no.” numbers indicating that they each have statistically significant homology to the ferredoxin query sequence (not too surprising since they are all different ferredoxins). Also note that the Smith-Waterman alignment algorithm does a best local alignment (more on this later) so the entire query sequence may not be presented in the output. Rather the part of the sequence that has a good alignment with the database entry is shown. The sequence is not aligned for regions where the significance of the alignment begins to decline. Hence in the example above, for the alignment to result #20, only amino acids 17 through 86 from the database sequence and amino acids 39 to 109 from

Figure 8.5: The webpage output from an MPsrch

the query sequence are shown in the alignment, even though the query protein is 128 amino acids in length. The sequence prior to amino acid 17/39 and after amino acid 86/109 are not considered to be part of the significant local alignment.

8.2 BLOCKS

The FASTA and BLAST servers are often searched for homologues in order to identify the query sequence. The **BLOCKS** server at <http://blocks.fhcrc.org> is designed to identify chunks of a protein that may encode some function. The BLOCKS server is thus somewhat related to the other servers mentioned above (and hence included here) but is designed to answer a different question. Instead of looking for similar sequences in the databases, it scans a database of protein motif signatures constructed from the **INTERPRO** database (a collection of protein families, domains and functional sites found in known proteins that can be applied to explore unknown protein sequences). In this way, BLOCKS will search a query sequence (must be protein or optionally, it will translate your nucleotide sequence to a protein) for similar protein motifs in known proteins. Blocks are defined as short ungapped (but potentially with variable length) segments of highly conserved regions of proteins. As of August 2003 the BLOCKS database website reports that it consists of 8656 block patterns (version 13.0, Aug 2001). This search is particularly useful for analysing distantly related proteins.

The web form to search the BLOCKS database is located at http://blocks.fhcrc.org/blocks/blocks_search.html (References should cite [S.Henikoff & J.Henikoff, 1991 Nucl.Acids.Res. 19:6565-6572](#)). Again simply supply the web page with your query sequence.

Since this search only makes sense for proteins, if a nucleotide sequence is supplied to the server, it will be translated in all frames. But a nucleotide sequence with IUBPAC ambiguity codes will be interpreted as a protein and will remain untranslated.

8.2.1 BLOCKS output

In the example below, I have searched the BLOCKS database with the sequence

```
> Ferredoxin
GIDPNYRTHKPVVGDSSGHKIYGPVESPKVLGVHGTIVGVDFDLCIADGSCITACPVNVF
QWYETPGHPASEKKADPVNQACIFCMACVNVCPVAAIDVKPP
```

The BLOCKS output begins with a lengthy informational message that I have deleted and then continues with the guts of the message.

3 possible hits reported

In this case, for ferredoxin, the program returns three possible hits. These are a 4Fe ferredoxin, a 7Fe Ferredoxin and a legume lectin alpha domain. The first signature consists of two parts (two blocks), the signature for the second hit consists of three parts (but only one was found in the query sequence) and the signature for the third hit consists of seven parts (but again only one is present in the query sequence). Each of these blocks is labelled A, B, C, etc. The E-values are calculated (as per the BLAST searches) to represent the expected number of hits with as good a similarity or better in a database of this size. Hence the last hit to a legume lectin alpha domain is probably just noise.

After this initial presentation, the program returns a diagram of hits. So in the first hit, the first block (A), can typically begin anywhere from the 1st to the 571st amino acid (in bone-fide proteins with this signature). In our query it begins at position 75. The second block (B), can occur anywhere from 0 to 338 amino acids distant from the first block. In our query sequence it is 0 amino acids away. Alignments of each of these blocks to a best match is shown.

For the second hit, the query contains two possible locations for the “C” block but non of the other blocks. For the third hit, only the “D” block.

8.2.2 Getting the Block

In addition to this the BLOCKS server will allow you access to information about the individual blocks found. You can get the entry either via links on their web page. The following output is are examples from their links.

From the BLOCKS database itself, it has the following information on the block.

```
Prints Database 37 in Blocks Format, Jun 2003
Made available by the Fred Hutchinson Cancer Research Center
1100 Fairview AV N, A1-162, PO Box 19024, Seattle, WA 98109-1024
Based on PRINTS Database as described by TK Attwood, et al (1994),
NAR 22(17):3590-3596. ID is from PRINTS gc line, AC is from
PRINTS gx line, DE is from PRINTS gt line, BL is BLOCK information.
Each PRINTS motif is represented by one block. For each segment, the
sequence ID is followed by the position of the first residue in the
segment. Sequence weights are shown to the right of each segment. The
higher the weight (maximum 100) the more dissimilar the segment is from
other segments in the block. These weights were obtained using the
position-based method of S Henikoff & JG Henikoff (1994), JMB 243:574-578.
Calibrated with position-specific scoring matrices made with pseudo-counts,
JG Henikoff & S Henikoff (1996), CABIOS 12(2):135-143.

Documentation
```

Ferredoxins [1] are a group of iron-sulfur proteins which mediate electron transfer in a wide variety of metabolic reactions. Ferredoxins can be divided into several subgroups depending upon the physiological nature of the iron-sulfur cluster(s). One of these subgroups are the 4Fe-4S ferredoxins, which are found in bacteria and which are thus often referred as 'bacterial-type' ferredoxins. The structure of these proteins [2] consists of the duplication of a domain of twenty six amino acid residues; each of these domains contains four cysteine residues that bind to a 4Fe-4S center.

A number of proteins have been found [3] that include one or more 4Fe-4S binding domains similar to those of bacterial-type ferredoxins. These proteins are listed below (references are only provided for recently determined sequences).

- The iron-sulfur proteins of the succinate dehydrogenase and the fumarate reductase complexes (EC 1.3.99.1). These enzyme complexes, which are components of the tricarboxylic acid cycle, each contain three subunits: a flavoprotein, an iron-sulfur protein, and a b-type cytochrome. The iron-sulfur proteins contain three different iron-sulfur centers: a 2Fe-2S, a 3Fe-3S and a 4Fe-4S.
- *Escherichia coli* anaerobic glycerol-3-phosphate dehydrogenase (EC 1.1.99.5) This enzyme is composed of three subunits: A, B, and C. The C subunit seems to be an iron-sulfur protein with two ferredoxin-like domains in the N-terminal part of the protein.
- *Escherichia coli* anaerobic dimethyl sulfoxide reductase. The B subunit of this enzyme (gene *dmsB*) is an iron-sulfur protein with four 4Fe-4S ferredoxin-like domains.
- *Escherichia coli* formate hydrogenlyase. Two of the subunits of this oligomeric complex (genes *hycB* and *hycF*) seem to be iron-sulfur proteins that each contain two 4Fe-4S ferredoxin-like domains.
- *Methanobacterium formicicum* formate dehydrogenase (EC 1.2.1.2). This enzyme is used by the archaeobacteria to grow on formate. The beta chain of this dimeric enzyme probably binds two 4Fe-4S centers.
- *Escherichia coli* formate dehydrogenases N and O (EC 1.2.1.2). The beta chain of these two enzymes (genes *fdnH* and *fdoH*) are iron-sulfur proteins with four 4Fe-4S ferredoxin-like domains.
- *Desulfovibrio periplasmic* [Fe] hydrogenase (EC 1.18.99.1). The large chain of this dimeric enzyme binds three 4Fe-4S centers, two of which are located in the ferredoxin-like N-terminal region of the protein.
- *Methanobacterium thermoautotrophicum* methyl viologen-reducing hydrogenase subunit *mvhB*, which contains six tandemly repeated ferredoxin-like domains and which probably binds twelve 4Fe-4S centers.
- *Salmonella typhimurium* anaerobic sulfite reductase (EC 1.8.1.-) [4]. Two of the subunits of this enzyme (genes *asrA* and *asrC*) seem to both bind two 4Fe-4S centers.
- A Ferredoxin-like protein (gene *fixX*) from the nitrogen-fixation genes locus of various *Rhizobium* species, and one from the *Nif*-region of *Azotobacter* species.
- The 9 Kd polypeptide of chloroplast photosystem I [5] (gene *psaC*). This protein contains two low potential 4Fe-4S centers, referred as the A and B

centers.

- The chloroplast frxB protein which is predicted to carry two 4Fe-4S centers.
- An ferredoxin from a primitive eukaryote, the enteric amoeba *Entamoeba histolytica*.
- *Escherichia coli* hypothetical protein yjjW, a protein with a N-terminal region belonging to the radical activating enzymes family (see <PDOC00834>) and two potential 4Fe-4S centers.

The pattern of cysteine residues in the iron-sulfur region is sufficient to detect this class of 4Fe-4S binding proteins.

Description of pattern(s) and/or profile(s)

Consensus pattern

C-x(2)-C-x(2)-C-x(3)-C-[PEG] [The four C's are 4Fe-4S ligands]

Sequences known to belong to this class detected by the pattern

the majority of known 4Fe-4S sequences, with very few exceptions.

Other sequence(s) detected in Swiss-Prot 24.

Note in some bacterial ferredoxins, one of the two duplicated domains has lost one or more of the four conserved cysteines. The consequence of such variations is that these domains have either lost their iron-sulfur binding property or bind to a 3Fe-3S center instead of a 4Fe-4S center.

Note the last residue of this pattern in most proteins belonging to this group, is a Pro; the only exceptions are the *Rhizobium* ferredoxin-like proteins which have Gly, and two *Desulfovibrio* ferredoxins which have Glu. It must also be noted that the three non 4Fe-4S-binding proteins which are picked-up by the pattern have Gly in this position of the pattern.

This is probably more information about ferredoxin than you would ever want. But should you desire more there are links to the INTERPRO entry for this domain. In this case it is (in part)

IPR006547; Nitrate reductase, beta subunit
Process [?] electron transport (GO:0006118)
Function [?] electron transporter activity (GO:0005489)
Abstract [?]
```

Ferredoxins are iron-sulphur proteins that mediate electron transfer

Figure 8.7: Typical results from an INTERPRO query

in a range of metabolic reactions; they fall into several subgroups according to the nature of their iron-sulphur cluster(s) [1, 2]. One group, originally found in bacteria, has been termed "bacterial-type", in which the active centre is a 4Fe-4S cluster. 4Fe-4S ferredoxins may in turn be subdivided into further groups, based on their sequence properties. Most contain at least one conserved domain, including four Cys residues that bind to a 4Fe-4S centre.

During the evolution of bacterial-type ferredoxins, intrasequence gene duplication, transposition and fusion events occurred, resulting in the appearance of proteins with multiple iron-sulphur centres: e.g. dicluster-type (2[4Fe-4S]) and polyferredoxins, iron-sulphur subunits of bacterial succinate dehydrogenase/fumarate reductase, formate hydrogenlyase and formate dehydrogenase complexes, pyruvate-flavodoxin oxidoreductase, NADH:ubiquinone reductase and others. In some bacterial ferredoxins, one of the duplicated domains has lost one or more of the four conserved Cys residues. These domains have either lost their iron-sulphur binding property, or bind to a 3Fe-4S centre instead of a 4Fe-4S centre. 3D structures are now known both for a number of monocluster-type [3] and dicluster-type [4] 4Fe-4S ferredoxins.

CAUTION: PRINTS signature in the current entry is known to miss protein matches and should be updated in the near future.

There is even a link to give a graphical interpretation of the block's taxonomic diversity and graphical demonstrations of the block's location within proteins as shown in Figure 8.7.

A really great resource.

8.3 SSearch

At the extreme slow end of database searchers is SSEARCH. This does a universal sequence comparison using the Smith-Waterman algorithm (T.F. Smith and M.S. Waterman, *J.Mol.Biol.* 147:195-197, 1981). That is, it is completely rigorous comparison of each sequence with the query sequence. This program uses code developed by X. Huang, R.C. Hardison, W. Miller (1990 *CABIOS* 6:373-381) for calculating the local similarity score and code from the ALIGN program (see below) for calculating the local alignment. SSEARCH is about 100-times slower than FASTA with ktup=2 (for proteins). The program itself is available for download as part of the [FASTA package of programs](#).

A study by [Pearson \(1995 *Protein Science* 4:1145-1160\)](#) compared the different methods of searching the protein databases. He found that the complete Smith-Waterman algorithm performed best to find distantly related homologies, followed by FASTA and then `blastp` when using suitable scoring matrices (BLOSUM55 – more on these later) and optimal gap penalties.

8.4 Why you should routinely check your sequence

The following is an example of why you should routinely do a search (FASTA, BLAST or whatever) for any new sequence that you are working on. This is a copy of a letter to the editor of NATURE.

Fact and fiction in alignment. NATURE 358:271, 1992

Sir - We have discovered a startling similarity between a dinosaur DNA sequence reported in the novel Jurassic Park¹ and a partial human brain cDNA sequence from the Venter laboratory described in Nature² (see figure).

The dinosaur sequence (DINO1) consists of duplication, with 117 base pairs from the first member of the repeat aligning with the human sequence, HUMXT01431, at the 95 per cent level of identity with only two gaps. The extraordinary degree of nucleotide sequence conservation between organisms as distantly related as dinosaur and human suggests strongly conserved function. Expression of HUMXT01431 in human brain raises the possibility that the dinosaurs were smarter than has been supposed, arguing against the hypothesis that their extinction resulted from lack of intelligence.

Our discovery also seems to raise the interesting legal question as to whether the copyright on Jurassic Park takes precedence over the pending patent on the human sequence. However, it appears that neither group is entitled to legal protection for its sequence, because both sequences also align with cloning vector pBR322, raising the possibility that both groups inadvertently sequenced vector DNA.
